Introduction

In temperate broadleaved forests of Europe and North America, the most common form of natural disturbance is fine scale gap dynamics driven by the death of individual (or a few) canopy trees (Peterken 1996, Splechtna et al. 2005). Less frequent natural disturbances that affect larger areas are responsible for shaping the natural coarse pattern of forests. In Europe, this group of natural disturbances includes windthrow and ice break which, depending on their size and intensity, may result in the destruction and renewal of individual forest stands or entire woodlands (Pickett and White 1985, Peterken 1996, Ulanova 2000, Splechtna et al. 2005, Nagel and Diaci

2006). Unfortunately, there is limited quantitative information on the natural disturbance regimes of European forests, because unmanaged old-growth forests are scarce after a long history of intense forest use and exploitation (Glatzel 1999, Parviainen 2005). In Eastern Central Europe, where more remnants of natural forests surscientific traditions focused on describing forest stand structures and on distinguishing forest community types, hence much less emphasis has been put on studying processes (Standovár and Kenderes 2003).

Much must information is available on the natural disturbance regimes of North American forests (Van Dyke 1999, Bragg et al. 2003). Ice break and windthrow

ABSTRACT

Tree stands of the Börzsöny Mts, Hungary, were hit by severe ice storm and very strong wind several times in the past decade. In this work we analyse the spatial behaviour and background causes of ice breaks. Affected areas were mapped by marking the homogeneous disturbance patches in the airborne photos that were taken after the disturbance event, and then we estimated the intensity of the damage in each patch by field observation. The role of variables describing tonography, stand characteristics and management were investigated Beside tonographic variables mixture ratio of beech, stand age and average slenderness had prominent role in the generation of ice break. Our results show that in addition to the natural processes forestry operations also increased the susceptibility of the affected areas. These forest stands dominated by beech woods, are almost pure and even-aged. The resulting stand structure promotes the growth of sensitive slender trees.

Keywords: natural disturbance, silvicultural system, CART, beech, Fagus sylvatica

INTRODUCTION

Forest management has changed both the composition and structure of the original forests. The direct effects of the widely used form of age-class forestry, i.e. uniform shelterwood system uncet encode on the wheely take term of age-causa toresary, i.e. unitorm shearwood system with large felling units (<u>Mathews 1991</u>) include altered age and thered and shear there shand structure as well as the lack of certain forest developmental phases (e.g. old decaying phases) and of several structural elements (e.g. large snags, logs, rootplates). The importance of most associate tree species and characteristic patter size of stand types have also been changed. In addition to these species and characteristic patch size of sum types have also been charaged. In addition to these direct effects, there are less obvious consequences. The potential change in susceptibility of trees to biotic and abiotic disturbances result in

changed spatial patterns of affected areas as well as changes in the severity of disturbances. Several studies showed that the occurrence of severe disturbances in managed temperate forests can be related to the effects of forestry operations that changed the composition and structure of can be related to the effects of torestry operations that changed the composition and structure of the tree stands (e.g. for wind disturbances Gardiner & Quine 2000, Gardiner et al. 2005). While studying the possible factors that contribute to the development of ice break several studies showed the effects of topographic position (Seitchabe et al. 1993, Warllow 1999, Mou & Warllow 2000, Rhoads et al. 2002, Millward & Kanft 2004), tree species (Lemon 1961, Helencon & Lechowicz 1987, Warllow 1999, Mou & Warllow 7000, Dugauy et al. 2001, Rhoads et al. 2002, Millward & Kanft 2004) and stand age (Rhoads et al. 2002). The effects of tending were also studied (Morris & Ostrowski 2005, <u>Brage et al.</u> 2003). In this paper we study the effects of two events of ice brake that hit the same managed forest area within 5 years (in January 1996 and 2001). We study the effects of topography, tree species composition and management related stand characteristics on the development of ice brake

for Quercus neighbourhoods. The growth-promoting effect

was significant on clay-poorer soil, but not on clay-richer soil

Tree species diversity in the neighbourhood tended to cor relate positively with mean stem growth and negatively with

the sensitivity to environmental fluctuation. We conclude that

the neighbourhood of a tree can influence its mean stem

increment and growth sensitivity to environmental fluctua-

tion in temperate mixed forests with the effect partly depending on the neighbours' species identity.

While plant-plant interactions have been studied in detail

in a multitude of natural and synthetic herbaceous plant communities, much less is known about the mechanisms of

tree-tree interactions and their consequences in mature

forests. Since more than a century, foresters have con

ducted growth trials investigating density effects on the yield of monospecific plantations (e.g. von Seebach 1845; Bohdanecký 1926; Assmann 1970; Plauborg 2004). These

studies have greatly improved our understanding of the

nature of intraspecific competition among woody plants and its dependence on stem density, canopy structural

properties, and nutrient and water availability (Piutti and

Cescatti 1997; Chen et al. 2003; Gouveia and Freitas 2008). Interspecific interactions in mixed tree plantation

have also received considerable attention with a focus on

European beech grows better and is less drought sensitive in mixed than in pure stands: tree neighbourhood effects on radial increment

Inga Mölder · Christoph Leuschner

Received: 10 July 2013/Revised: 9 January 2014/Accepted: 1 February 2014/Published online: 27 February 2014 © Springer-Verlag Berlin Heidelberg 2014

Abstract

Key message Tree neighbourhood can affect the radial increment of Fagus sylvatica and its sensitivity to environmental fluctuation, which partly depends on soil clay content and species identity of the neighbours. Abstract In a temperate deciduous forest, we analysed the tree ring chronologies of 152 Fagus sylvatica L. target trees from tree neighbourhoods varying in species composition and tree diversity. We hypothesised that the species identity of the neighbour trees influences radial stem increment and environmental sensitivity of growth of the target trees. Further, we postulated that the effect was stronger under low abiotic stress as expressed by soil clay content and that beech individuals could have a higher wood production in mixed than in monospecific stands. We measured radial increment and analysed the growth response to, and recovery from, selected stress events. Fagus trees in a neighbourhood with more than 30 % of the canopy's 'influence sphere' occupied by allospecific trees had a higher mean stem increment, a lower increment sensitivity to environmental fluctuation and a smaller erowth depression after the 1976 drought than beech trees surrounded by conspecific trees. We found that beech neighbours' identity can influence beech growth: positive effects on mean increment and a reduced sensitivity were found for Tilia, Fraxinus and Acer neighbourhoods, but not

Abstract

The impact of invasive herbivore species may be lower in more diverse plant communities due to mechanisms of associational resistance. According to the "resource concentration hypothesis" the amount and accessibility of host plants is reduced in diverse plant commu-nifies, thus limiting the exploitation of resources by consumers. In addition, the "natural enemy hypothesis" suggests that richer plant assemblages provide natural enemies with more complementary resources and habitats, thus promoting top down regulation of herbivores. We tested these two hypotheses by comparing crown damage by the invasive Asian chestnut gall wasp (*Dryccormus kurphilus*) on chestnut trees (*Castanea sativa*) in pure and mixed stands in Italy. We estimated the defoliation on 70 chestnut trees in 15 mature stands sampled in the same region along a gradient of tree species richness ranging from one spe-cies (chestnut monocultures) to four species (mixtures of chestnut and three broadleaved species). Chestnut defoliation was significantly lower in stands with higher tree diversity. Damage on individual chestnut trees decreased with increasing height of neighboring, heterospecific trees. These results suggest that conservation blogical control method based on tree species mixtures might help to reduce the impact of the Asian chestnut gall.

A rich body of theory has been developed to predict the effects of plant diversity on communities at higher trophic levels and the mechanisms underpinning such effects. However, there are mechanisms underpinning such effects, However, mere are currently a number of key gaps in knowledge that have hindere the development of a predictive framework of plant diversity effects on consumers. For instance, we still know very little about how the magnitude of plant trait variation (e.g. intraspecific vs. inter-specific), as well as the identity and combined specie vs. inter-specine), tas were as no identify and compand effects of plant, herbivore and natural enemy traits, mediate plant diversity effects on consumers. Moreover, the fine-scale mechanisms (e.g. changes in consumer behaviour or recruitment responsely underlying such diversity effects in many cases remain elusive or have been overlooked. In addition, most studies of plant diversity effects on associated consumers have been developed under a static, unidirectional bottom-up) framework of effects on herbivores and predator bottom-up) tranework or effects on nerbivores and predators without taking into account the potential for dynamic feedbacks across trophic levels. Here we seek to address these key gaps in knowledge as well as to capitalize on recent advances and emerging frameworks in plant biodiversity research. In doing so we provide new insights as well as recommendations which will stimulate new research and advance this field of study.

Introduction The consequences of plant intra-specific and inter-sp cific diversity on associated faunas have been the focus of citic diversity on associated faunas have been the focus of much research over the last decade (e.g. $[1^{+*}_{--}=8,9^{+*}]$). Studies have found that plant diversity positively influ-ences arthropod diversity and abundance [3,4,8,10], and alters plant-arthropod and arthropod-arthropod interac-tions [5,7,11,12]. These findings emphasize that conserving and manipulating plant diversity in natural and managed systems, respectively, is crucial for maintaining ecosystem function [13–15].

A rich body of theory has been developed to predict the

effects of plant diversity on communities at higher trophic errects of plant events on communities at nigher roome levels (116-22), see Box 1). Despite this was collection of theory behind plant diversity effects on associated faunas and the large number of empirical studies conducted thus far, formal evaluations of the mechanisms behind the observed patterns have been developed in natural com osserved partents have been developed in natural com-munities (but see [20] for c.g. in agricultural systems). In addition, there are also a number of key gaps in knowl-edge that have hindered the development of a predictive framework of plant diversity effects on higher trophic levels (Figure 1). For example, we generally ignore how levels (right). For example, we generally ignore now the magnitude of variation in plant traits (e.g. inter-specific vs. intra-specific diversity) or the identity (includ-ing independent and interactive effects of multiple traits) of plant traits determines such effects. Similarly, many studies have lacked an explicit evaluation of the influence stores have taken an expiret evaluation of the immerice of herbivore traits such as diet breadth, mobility and feeding behaviour, and the underlying mechanisms for diversity effects on consumer abundance or behaviour remain clusive (e.g. effects of diversity on consumers via increased plant growth vs. increased habitat heterogene increased plant growth vs. increased habitat heterogene-ity). Finally, most empirical studies of plant diversity effects on associated faunas have been developed under a static, unidirectional (bottom-up) framework of effects on herbivores and predators, ignoring the intrinsic dyna-mism in the form of feedbacks between the hottom-up effects of plant diversity and top-down effects by con

Keywords: Ecosystem service Pest control Predation Leaf damage Forest structure Forest management

ABSTRACT

Controlling herbivore insects by insectivorous birds is a major ecosystem service, nevertheless little is known about how local habitat features and forest management influence the efficiency of this service and about how the pest control service birds provide can be maintained and improved. We conducted an experiment in temperate oak forests in the Mátra Mountains, northern Hungary to measure bird predation rate of artificial caterpillars resembling winter moth (*Operophtera brumata* L.) larvae, to evaluate the relationships among insectivorous bird communities, caterpillar populations and leaf damage caused by caterpillars and to assess the effect of forest heterogeneity on these processes. We found, that structurally heterogeneous forests maintained a significantly higher abundance of insectivorous birds. Especially the tree size heterogeneity increased bird abundance. The rate of bird predation was positively related to the abundance of insectivorous birds as well as to caterpillar abundance, which indicates that birds were able to respond to caterpillar density. We were not able to demonstrate a direct negative effect of bird predation on caterpillar abundance and a positive effect of caterpillar abundance on leaf damage. Structurally heterogeneous forests, however, suffered from less leaf damage than did homogeneous for-

More details (just to mention a few):

Wiser and higher resolution soil site/tree species choice

Increasing intraspecific diversity

-Natural regeneration is better than artificial -,,Climate matching/assisted migrations"

Increasing interspecific diversity

-Mixed stands instead of monocultures -Supporting earlier neglected native tree and shrub species, even the presecuted "weed trees"

Increasing the structural diversity

-Small scale cutting areas -Increasing size and age diversity -Leaving dead wood in the foress

Alternative forest management systems

Water retention where possible

Proactive (preventive) instead of reactive forest protection

Water in Forests

A brief summary

-Almost all damage types show an increasing trend in the last 50 years in Hungary, even in percentage of the actual forested area.

-Health status of our forests strongly depends on the weather conditions, but the forest management practices also have major effect on it.

-The climate change scenarios (more frequent and more severe droughts, and extreme meteorological events) therefore predict even further negative trends in forest health.

-The "story" is not restricted to Hungary. Similar problems and trends are known worldwide.

Making our forests more resistant/resilient is extremely important and unavoidable!

We need mor knowledge, we need more research!

Thanks for your attention!
